THE ARACHNID FOSSIL RECORD

P. Selden

Department of Extra-Mural Studies, The University, Manchester M13 9PL.

Arachnids belong to the arthropod phylum Chelicerata which, in addition to the scorpions, spiders, mites and others, embraces the extinct eurypterids, the king-crabs (Xiphosura), and arguably the pycnogonids (sea-spiders). Before presenting a review of the recent discoveries which extend and modify the traditional picture of arachnid evolution, let us first look at the eurypterids and king-crabs.

The eurypterids, or sea-scorpions, are known from rocks ranging from Ordovician to Permian in age (Fig. 1) but are most abundant in upper Silurian strata in Britain, Scandinavia and the USA. Indeed, their distinctive appearance (scorpion-like but with broad swimming paddles in place of the last pair of legs) and abundance in Silurian limestones in the north-east USA has earned one species, *Eurypterus remipes* De Kay the title of State Fossil of New York. This part of the world has also yielded the giant *Buffalopterus* which at 2 m in length was the largest arthropod which ever lived. Its fearsome, huge chelicerae exemplify just one of the methods of prey-capture of these giant carnivores of mid-Palaeozoic seas. Though rare as fossils, eurypterids are usually very well preserved, and one species, *Baltoeurypterus tetragonophthalmus* (Fischer), has provided a wealth of information about the mode of life and palaeoecology of these fascinating animals (Selden, 1981, 1984).

Traditionally allied with the eurypterids in the class Merostomata are the king-crabs, typified by the living *Limulus polyphemus*. The oldest xiphosurans are Cambrian in age, and forms closely similar in morphology and ecology to the living species have been found in rocks as old as Carboniferous, hence *Limulus* is often dubbed a 'living fossil'. The oldest member of the superfamily Limuloidea was described recently from Scotland (Waterston, 1985), and a slightly younger but giant form is now known from Weardale (Siveter & Selden, 1987).

Scorpions have generally been considered the most primitive of arachnids; many authors (e.g. Bristowe, 1958; Grasshoff, 1978) have considered them as the sister-group of the eurypterids, in which case the eurypterids must be included in the Arachnida, or the scorpions excluded from that group. Alternative opinions (Boudreaux, 1979; Weygoldt, 1980; Weygoldt & Paulus, 1979) place the eurypterids as the sister-group of the arachnids (including scorpions); under either scheme, the Merostomata becomes an unnatural group.

Modern scorpions are mainly tropical, nocturnal, terrestrial animals particularly adapted to arid environments and are classified into less than a dozen families. However, fossil scorpions are known from rocks as old as late Silurian; at that time they lived in water alongside their eurypterid relatives, and aquatic scorpions persisted possibly into Mesozoic times. Air-breathing scorpions apparently appeared in the early Carboniferous, and scorpions were at their most diverse in the late Carboniferous when 25 families have been recognized (Kjellesvig-Waering, 1986). Living scorpions can be searched for at night with a blacklight, since they fluoresce in ultraviolet light. This is a property of one layer in their exoskeleton: the hyaline exocuticle. Hyaline exocuticle seems to be unique to scorpions, but is possibly present in eurypterids and king-crabs also. Scraps of scorpion cuticle are abundant in coals and related sediments to the exclusion of all other arthropods, a phenomenon which is attributed to the inertness of the hyaline exocuticle (Bartram et al., 1987) and helps to explain the relative abundance of scorpions amongst arachnid fossils.
Other arachnids have very sporadic fossil records (Fig. 1), though there is a general trend which can be attributed almost entirely to the time distribution of the rare localities in which they are found. Spiders are abundant in some Tertiary (Palaeogene and Neogene) ambers (Oligocene, Baltic and Dominican Republic for example), and are known from shales of the same age in Colorado. Tertiary faunas

Fig. 1. Known stratigraphic ranges of the major groups of chelicerates, from published and unpublished data. Solid lines indicate fairly continuous occurrence, dashed lines indicate data poor or lacking. Solid circles mark only or most important occurrences, open circle indicates uncertain occurrence.
are more similar to those of today than to Mesozoic and Palaeozoic faunas. The end-
Cretaceous mass extinction brought the Mesozoic era to a close and the faunal and
floral changes across this boundary are great. Unfortunately, Mesozoic arachnids are
exceptionally rare, so we cannot be sure whether the same is true of them. Incidentally, Cretaceous ambers are known from Canada and the Lebanon which
contain spider inclusions, so it may not be very long before we have enough well
preserved specimens to test this hypothesis.

In the last few years, four spider specimens from early Cretaceous lithographic
limestone of the Sierra de Montsec in north-east Spain have been discovered. This
locality has long been famous for its beautifully preserved plants, insects, amphibians, and especially bird feathers. Three of the spiders are mature males with
their distinctively elaborate palps, and the fourth has characters which could place it
in a modern family. A major problem with these Mesozoic spiders is that the details
needed to place them in the classification scheme for Recent spiders are not always
preserved. In a Jurassic example (Eskov, 1984), a combination of characters of
numerous living families was observed which resulted in the setting up of a new
‘extinct’ family.

Travelling further back in time we pass the end-Permian extinction event, the most
severe of all, and come to the late Carboniferous. Ironstone nodules in coal measure
rocks of Europe and North America have yielded an abundant terrestrial and near-
shore fauna, including crustaceans, insects, millipedes, xiphosurans and arachnids.
Particularly interesting are the 20 or so specimens of ricinuleids. Ricinuleids are
charming little thick-skinned arachnids which creep amongst leaf litter under logs
and in caves in the American and West African tropics. There are about 50 living
species in three genera. The Carboniferous ricinuleids are remarkably similar to the
living forms; an interesting difference being that the fossils show two pairs of eyes in
the position on the living animals where vestigial eye-spots are present (Selden,
1986).

Another group of arachnids relatively well-represented in Coal Measure rocks are
the extinct trigonotarbids. These animals are very close to spiders in their
morphology, but lack spinning organs. Trigonotarbids are also a major component
of the terrestrial faunas of three important Devonian localities: the Rhynie chert of
Aberdeenshire; Alken-an-der-Mosel, Germany; and Gilboa, New York. Hirst
(1922) described the Rhynie fauna, a bog habitat of early vascular plants rapidly
gulfed in hot, siliceous waters from nearby volcanic eruptions. The Rhynie chert
contains the oldest terrestrial fauna known, and includes a springtail, a mite, numerous trigonotarbids, and a possible spider (see Rolfe, 1980 for review of this
and other early terrestrial faunas). The Alken fauna includes both terrestrial
(trigonotarbid, myriapod) and amphibious (eurypterid) elements (Størmer, 1970–
6).

More recently, palaeobotanists Bonamo and Grierson were dissolving grey
siltstones from the Devonian of Gilboa, New York for early terrestrial plants when
they came across an extremely varied fauna of early land animals (Shear et al., 1984;
Shear, 1986). Again, trigonotarbids are very common (Shear & Selden, 1986), but
there is also evidence of insects, myriapods (the earliest centipede), scorpions, and
mites. The fossils are beautifully preserved, and when mounted in balsam and
viewed in transmitted light, minute details of setae, trichobothria, slit sensillae,
lyriform and other sense organs are clearly visible (see Shear et al., 1988).

One element of the fauna caused the greatest modification to the arachnid fossil
record when first discovered. Two beautiful little creatures, described by the
assistant who found them as ‘little dragons’, turned out to be pseudoscorpions.
Virtually identical in all aspects to living pseudoscorpions, the find of these Devonian forms pushes the fossil record of the group back tenfold.

Exciting though these finds of rare, earliest terrestrial arachnids are, their importance to Zoology extends beyond that to Arachnology alone. They help us to understand how the very first land animals pioneered the empty terrestrial habitat 400 million years ago. It was these pioneers which paved the way for the rich and varied arthropod fauna which abounds in our countryside today.
